## SIMULATOR STUDY OF COUPLED ROLL-SPIRAL MODE EFFECTS ON LATERAL-DIRECTIONAL HANDLING QUALITIES

By William D. Grantham, Frederick L. Moore, Perry L. Deal, and James M. Patton, Jr.

Langley Research Center

#### SUMMARY

A piloted fixed-base simulator study has been made to provide a preliminary determination of the effects of a coupled roll-spiral mode on lateral-directional handling qualities. The coupling of the roll and spiral modes is characterized as an unconventional lateral oscillatory mode and has only recently become of interest since conventional aircraft have not displayed this phenomenon. No attempt is made in the present study to establish any kind of handling-qualities criteria because of the limited scope of the investigation, including the limitations of fixed-base simulation.

The results indicate that when the conventional roll and spiral modes couple, the lateral-directional handling qualities are seriously degraded regardless of how the coupling was brought about, that is, regardless of which aerodynamic derivative or combination of derivatives caused the two modes to couple. When this coupling occurs, regardless of the cause of the coupling, the pilot sees a serious degradation in roll damping. The comments made by the pilots and the pilot ratings assigned to the various configurations evaluated seemed to correlate somewhat in terms of the frequency of the roll-spiral mode in that "acceptable" pilot ratings  $\left(6\frac{1}{2} \text{ or less}\right)$  were more probable if the frequency of the coupled roll-spiral oscillatory mode was greater than 0.35 rad/sec, and indications were that this frequency should not be greater than approximately 1.0 rad/sec. There did not seem to be any definite trend regarding the magnitudes of the damping ratio of the coupled roll-spiral oscillatory mode or damping ratio of the Dutch roll mode required for satisfactory pilot ratings.

#### INTRODUCTION

Radically different types of aircraft can have modes of motion which are so different from those experienced by conventional aircraft that they cannot be evaluated prior to some form of simulation or actual flight tests. This, of course, causes extreme difficulty in the evaluation of possible problem areas during the development of new types of aircraft. One such problem which has occurred recently with such widely diverse types of

aircraft as the supersonic transport, the V/STOL, and the piloted reentry vehicles is that an unconventional lateral oscillatory mode, which is brought about by the coupling of the conventional roll and spiral modes, may be experienced. Only very limited information is available concerning the effects of such roll-spiral coupling on the flight characteristics of airplanes since conventional aircraft have not displayed this phenomenon.

Reference 1 presents the results of a fixed-base-simulator study of the lateral-directional handling qualities of a hypothetical fighter airplane having roll-spiral coupling. The general conclusion drawn from that study was that an aircraft with roll-spiral coupling would have unacceptable handling qualities. The results of reference 1 are considered to be limited in application, however, since (1) only a fighter-type airplane at a high altitude, 30 000 ft (12 km), and a high airspeed (Mach number of 1.2) was considered and (2) the roll damping derivative  $C_{\c lp}$  was, in general, the main parameter varied in order to cause the coupled mode.

Because of the lack of adequate information with which to predict the acceptability of the lateral-directional handling qualities of aircraft having roll-spiral coupling, the present study was made to provide a preliminary evaluation of the problem. This study consisted of a fixed-base simulator study in which the aerodynamic characteristics of the simulated aircraft were varied in such a way as to obtain a coupled roll-spiral mode in various ways and with varying specific characteristics. The simulator tests were made for two sets of initial conditions, a subsonic cruise condition and a landing-approach condition. No attempt was made to establish any kind of handling-qualities criteria; the aim of the present study was simply to generate information that will be of use in preflight evaluation of the flying qualities of an aircraft having a coupled roll-spiral mode within its normal flight envelope.

#### SYMBOLS

The units for the physical quantities used herein are presented in both the U.S. Customary Units and the International System of Units (SI). All aerodynamic coefficients and moments of inertia are referred to principal body axes.

#### GENERAL DISCUSSION ON ROLL-SPIRAL COUPLING

From the lateral-force, rolling-moment, and yawing-moment equations of motion, the characteristic equation describing the lateral-directional open-loop flight motions of an aircraft is determined and is of the form

$$C_1s^4 + C_2s^3 + C_3s^2 + C_4s + C_5 = 0$$

This quartic equation usually can be factored as follows:

$$\left(\mathbf{s}^2 + 2\zeta_{\mathbf{D}}\omega_{\mathbf{D}}\mathbf{s} + \omega_{\mathbf{D}}^2\right)\left(\mathbf{s} + \frac{1}{\mathsf{t_R}}\right)\left(\mathbf{s} + \frac{1}{\mathsf{t_S}}\right) = 0$$

The quadratic has a complex conjugate pair of roots and is called the Dutch roll mode. The two real roots are referred to as the roll and spiral aperiodic modes of motion, respectively. The roll-mode root usually has a dominant effect on the initial bank-angle response to aileron inputs, whereas the spiral-mode root usually has a dominant effect on the long-term bank-angle characteristics. Therefore, the magnitudes of the four roots of the characteristic equation affect the lateral-directional response of an aircraft, which in turn affects the pilot's assessment of the flying qualities of that aircraft.

As mentioned previously, it is anticipated that some of the V/STOL, supersonic transport, and piloted reentry configurations that have been proposed may experience an unconventional lateral oscillatory mode which is brought about by the coupling of the conventional roll and spiral modes. That is, for certain combinations of the aerodynamic stability derivatives of a given aircraft, the aforementioned characteristic equation will have two complex conjugate pairs of roots instead of the conventional one complex conjugate pair of roots and two real roots. When this occurs, the characteristic equation would have the factored form

$$\left(\mathbf{s^2} + 2\zeta_{\mathbf{D}}\omega_{\mathbf{D}}\mathbf{s} + \omega_{\mathbf{D}}^2\right)\left(\mathbf{s^2} + 2\zeta_{\mathbf{RS}}\omega_{\mathbf{RS}}\mathbf{s} + \omega_{\mathbf{RS}}^2\right) = 0$$

The first quadratic (subscript D) is the previously mentioned Dutch roll oscillation, and the second quadratic (subscript RS, roll-spiral) represents the second complex conjugate pair of roots and usually describes a long-period oscillation (P > 20 sec) which has sometimes been termed a lateral phugoid (ref. 1, for example). This second oscillation is brought about when (1) there is an unusually large or small value of a particular aerodynamic stability derivative or (2) there is a certain combination of several of the aircraft's static and dynamic aerodynamic stability derivatives.

When the aerodynamics are of such a nature that the roll and spiral modes couple, the resulting oscillation will affect the pilot's control of bank angle. The pilot normally controls bank with ailerons commanding a roll rate. However, when the coupled roll-spiral mode is experienced, the pilot may see the ailerons commanding either roll acceleration (low  $\omega_{RS}$ ) or roll attitude (high  $\omega_{RS}$ ). Figure 1 illustrates these three different types of response to a step aileron input.

The root-locus method is a graphical procedure that allows the variation in the roots of an equation to be shown, on a complex plane, as the coefficients of the equation change. (Fig. 2 shows the features of the complex plane as applied to dynamic systems.) Figure 3 presents a root-locus plot which illustrates a case in which the conventional roll and spiral modes couple and form a second oscillatory mode as the aircraft's stability derivatives are arbitrarily varied. Some of the results of this study are presented with the root-locus graphical technique and are discussed subsequently.

#### SIMULATOR

The simulator presented the pilot with the essential elements of flying under instrument conditions. The cockpit was equipped with a stick-type pitch and roll control, conventional rudder pedals, a single lever thrust controller, and flight instruments arranged in the standard basic "T." (See fig. 4.) The simulator did not incorporate cockpit motion and no external visual display was used. Control forces were provided by springs. The maximum travel of the controls, control breakout forces, and control-force gradients are presented in table I. A general-purpose analog computer was used with the simulator and was programed with the equations of motion for six degrees of freedom shown in the appendix. These equations represent motions along and about the airplane body axes.

#### TEST CONFIGURATIONS AND CONDITIONS

For the present study, a hypothetical light transport airplane was considered. The airplane was heavily loaded along the fuselage  $(I_X < I_Y)$ , and the mass and dimensional characteristics are presented in table II. The simulator tests were made in two phases: one for conditions representative of cruise flight and one for conditions representative of the landing approach. Specifically these conditions are

Phase I – the airplane was considered to be initially at an altitude of 20 000 feet (6.1 km) and trimmed for straight and level flight at an angle of attack of  $3.85^{\circ}$  and a true airspeed of 400 knots.

Phase II — the airplane was considered to be in the landing-approach configuration and initially at an altitude of 2000 feet (610 m) and trimmed for straight and level flight at an angle of attack of  $15^{\rm O}$  and a true airspeed of 135 knots.

The lateral aerodynamic characteristics of the basic configurations are presented in table III. No longitudinal characteristics are presented because the longitudinal handling qualities of the basic configurations were adjusted until they were rated by the pilots to be very satisfactory (a pilot rating of  $2\frac{1}{2}$ ) before the evaluation of the effects of roll-spiral coupling began. The aerodynamic characteristics of the other configurations were varied during the investigation as shown by the values of the aerodynamic stability derivatives listed in table IV. For the most part, the variations made in the lateral-directional aerodynamic derivatives during this study were arbitrary but were considered to be within a realistic range. Table IV also presents the dynamic stability characteristics of the various configurations evaluated during the two phases of simulated flight. The dynamic stability characteristics presented in tables III and IV were determined from calculations based on classical linearized equations of motion.

#### **EVALUATION PROCEDURES**

Since this study was concerned solely with the evaluation of the lateral-directional flying qualities, an attempt was first made to optimize the values of the longitudinal aero-dynamic parameters required for satisfactory handling qualities of that axis. As a result, the longitudinal axis was assigned an overall pilot rating of  $2\frac{1}{2}$  and was not considered to influence the pilots' evaluation of the lateral-directional handling qualities.

Each test configuration was established by varying the magnitudes of the necessary lateral-directional aerodynamic coefficients so that the required frequency and damping of both the Dutch roll mode and the roll-spiral coupled mode were achieved. (Whenever possible, the frequencies and damping ratios were varied from low values to high values in incremental steps.) The general handling qualities of the configurations were evaluated in level flight for both the phase I and phase II conditions, and for the phase II conditions, the configurations were also evaluated for the instrument landing system (ILS) approach task.

The pilots evaluated each test configuration separately but were not informed of the parameters being varied. An effort was made to set up the order of tests so that changes in consecutive conditions were gross enough to be clearly different. The pilots also reevaluated the basic configuration whenever desired in order to retain a reference. Two pilots participated in the simulation program; unfortunately, the number of test conditions that were "flown" by both pilots was much less than desired. Most of the conditions tested during phase I of the program were evaluated by pilot A, and most of the conditions during phase II were evaluated by pilot B. No complete listing of all of the pilot comments for each configuration evaluated is presented, but table IV indicates the pilots' major objections to each configuration.

#### General Flying Qualities

Standard flight test procedures and techniques (ref. 2) were used in the evaluation of the lateral-directional flying qualities of each test configuration and condition, and a pilot rating was assigned to each case, with appropriate pilot comments. See table V for the pilot rating system used. The lateral-directional characteristics evaluated are as follows:

- (1) Control powers
- (2) Response and sensitivity
- (3) Roll damping
- (4) Dutch roll oscillations
- (5) Adverse-proverse yaw
- (6) Spiral stability

- (7) Heading control in turn entry and recovery
- (8) Directional stability
- (9) Dihedral effect
- (10) Lateral oscillation characteristics
- (11) Bank-angle control

#### Instrument Landing System Approach Task

The ILS approach was initiated with the airplane in the power-approach condition (power for level flight) at an altitude of 2000 feet (610 m), a true airspeed of 135 knots, and 8.5 nautical miles (15.8 km) from the runway. The cockpit indicator presented localizer and glide-slope deviation only, and the initial conditions placed the airplane offset to the left of the localizer and below the glide slope. The glide-slope angle used during the study was 2.7°. The pilot's initial task was to turn to intercept the localizer, and then when the glide slope was captured, the pilot attempted to maintain both the localizer and glide slope as closely as possible until the 200-foot (61 m) altitude termination point was reached.

#### RESULTS AND DISCUSSION

As stated previously, the present study was conducted to obtain a preliminary determination of the effects of the coupling of the roll and spiral modes on the lateral-directional handling qualities of a hypothetical light transport airplane. Also, although no attempt is made to establish any kind of handling-qualities criteria, the intent of this paper is to present information that will be of use in preflight evaluation of the flying qualities of an aircraft that has a coupled roll-spiral mode within its normal flight envelope. The results of the study are, for the most part, presented and discussed in relation to pilot ratings and opinions. It should be mentioned that although a complete pilot assessment of the lateral-directional flying qualities were made for each test condition, the pilot's evaluation of bank-angle control is given the most attention in the discussion since the coupling of the roll and spiral modes has a predominant effect on bank-angle control.

#### Phase I - Cruise Condition

Basic configuration.— The lateral-directional dynamic stability characteristics of the basic configuration are presented in table III. Both pilots assigned a pilot rating of 2 to the lateral-directional handling qualities of this basic configuration. The pilots stated that the lateral control characteristics were excellent, that the Dutch roll and adverse-proverse yaw characteristics were satisfactory, and that the heading control in a turn entry and recovery was good. Figure 5 presents a time history of the motion obtained for an aileron step input.

The only objectionable handling qualities of the basic configuration were:

(1) The spiral characteristics were less than good – although  $t_{1/2} \approx 21$  seconds, the pilots felt that the spiral mode was too stable.

(2) The harmony between the longitudinal and lateral stick forces was less than desired — the pilots would have preferred a slight reduction in the lateral stick force or a slight increase in the longitudinal stick force.

No changes were made in these characteristics, however, since table V describes a rating of 2 as "good enough without improvement."

Effects of variations in aerodynamic derivatives on stability characteristics.—Reference 1 states that a coupled roll-spiral mode can exist if an aircraft has low roll damping  $C_{lp}$  and low directional stability  $C_{n\beta}$ , especially if the effective dihedral parameter  $C_{l\beta}$  is large. In addition, reference 3 states that the magnitude of  $C_{np}$  must be considered. For example, it is stated in reference 3 that when  $C_{lp}$  is at least that required for satisfactory "ideal" roll control ( $t_R \leq 1.2 \text{ sec}$ ), the possibility of roll-spiral coupling would normally be confined to low  $C_{n\beta}$  in combination with very high  $C_{l\beta}$  and positive  $C_{np}$ .

The four aforementioned derivatives  $C_{l\beta}$ ,  $C_{n\beta}$ ,  $C_{lp}$ , and  $C_{np}$  as well as two additional derivatives  $C_{nr}$  and  $C_{lr}$  were considered in the present study to establish the various conditions  $\omega_D$ ,  $\zeta_D$ ,  $\omega_{RS}$ , and  $\zeta_{RS}$  to be evaluated by the pilots. The conditions were chosen so that the frequencies and damping ratios would be varied from low values to high values, in incremental steps, whenever possible. An example of how the variation in these derivatives, one at a time, can affect the dynamic stability characteristics of the airplane used in the present study is shown in figure 6. The root-locus technique is used to present this information, and with only a brief glance at figure 6, the following effects of the stability derivatives are noted:

Parameter varied	Direction	Can cause roll-spiral coupling
$c_{l_{\mathcal{B}}}$	More negative	Yes
$egin{array}{c} \mathbf{c}_{l_{oldsymbol{eta}}} \ \mathbf{c}_{\mathbf{n}_{oldsymbol{eta}}} \end{array}$	Less positive	No
$C_{lp}$	Less negative	Yes
$C_{n_p}$	More positive	Yes
$c_{l_{\mathbf{r}}}$	Less positive	No
$C_{n_r}$	More negative	No <sup>1</sup>

 $<sup>^1\!\</sup>mathrm{Although}$  increasing the yaw damping will not cause the roll and spiral modes to couple on the airplane used in this study, very large values of  $C_{n_r}$  will cause all modes to become aperiodic.

Effects of coupled roll-spiral mode. When the conventional roll and spiral modes couple, the lateral-directional handling qualities are seriously degraded regardless of how the coupling was brought about, that is, regardless of which aerodynamic derivative or combination of derivatives caused the two modes to couple. This result is illustrated by the fact that the pilot ratings given in table IV for all the modified configurations are markedly worse than those for the basic configurations. In fact they were  $3\frac{1}{2}$  or greater, compared with a rating of 2 for the basic configuration (configuration I-1). Although sometimes there were many factors involved that made the handling qualities less than desired, one factor that the pilots always complained about was the apparent lack of roll damping; this point was always mentioned by the pilots regardless of the magnitude of  $C_{l_D}$  if the roll and spiral modes were coupled.

Various parameters were examined to determine whether there were any factors that could be correlated and thus provide a means for assessing the degree of degradation of the handling qualities that could be expected prior to flight tests of an aircraft. The parameters examined were  $\omega_{RS}$ ,  $\zeta_{RS}$ , and  $\zeta_{D}$ . Only  $\omega_{RS}$  seemed to provide any broad correlation. The frequency of the coupled roll-spiral mode  $\omega_{RS}$  varied from 0.10 to 1.39 rad/sec for the various conditions covered during the present study, and the pilot ratings along with their major objections to each condition are presented in table IV. Figure 7 presents a plot of  $\omega_{RS}$  against pilot rating for the various conditions tested. (It can be noted from table IV that the damping of both the coupled roll-spiral mode and the Dutch roll mode was always positive.) The comments made by the pilots and the pilot ratings assigned to the various configurations indicated that "acceptable" ratings  $\left(6\frac{1}{2}\right)$  or less were more probable if  $\omega_{RS}$  was greater than 0.35 rad/sec.

When the frequency of the coupled roll-spiral mode  $\,\omega_{RS}\,$  was approximately 0.30 rad/sec or less, the pilots consistently stated

- (1) The damping in roll was very low or nonexistent
- (2) The airplane was overly responsive to lateral inputs
- (3) The airplane exhibited high proverse yaw for lateral inputs When the frequency of the coupled roll-spiral mode  $\omega_{RS}$  was as much as 0.40 rad/sec but less than 1.0 rad/sec, the pilots generally stated
  - (1) The damping in roll was low or moderately low
  - (2) The spiral stability was much too strong
  - (3) There was no evidence of proverse-adverse yaw

When  $\omega_{\rm RS}$  was very high (approximately 1.0 rad/sec or greater), the pilot indicated disapproval because the spiral mode was much too stable and the roll control effectiveness was no longer sufficient to maneuver the airplane adequately. This set of circumstances ( $\omega_{\rm RS} > 1.0~{\rm rad/sec}$ ) was documented for only one condition, configuration I-8

where  $\omega_{RS}$  = 1.39 rad/sec; but when the pilot "flew" this configuration, he stated: "By applying the lateral control slowly, a maximum of 30° bank angle can be attained and held with full lateral control." This result was not surprising, however, since it is obvious that the higher the frequency of the oscillation the quicker the roll rate will become zero.

The damping of the coupled roll-spiral mode  $\zeta_{RS}$  and the damping of the Dutch roll mode  $\zeta_D$  varied from approximately 0.10 to 1.0 for the conditions covered in phase I of the present study (h = 20 000 ft (6.1 km) and V = 400 knots) and there did not seem to be any definite trend of pilot rating with the magnitude of  $\zeta_{RS}$  or  $\zeta_D$ .

#### Phase II - Landing-Approach Condition

<u>Basic configuration.</u> Pilots A and B assigned pilot ratings of  $2\frac{1}{2}$  and  $3\frac{1}{2}$ , respectively, to the lateral-directional handling qualities of this configuration (configuration II-1) for both the "air work" and the ILS approach. Both pilots stated that the roll control, in general, was good and that the roll damping and the damping of the Dutch roll oscillation were both good. The only adverse comments involved heading control and lateral stick force; the pilots stated that the amount of adverse yaw and the magnitude of the lateral stick force were higher than desired.

Effects of coupled roll-spiral mode. As was the case for phase I, when the roll and spiral modes coupled, the lateral-directional handling qualities were seriously degraded regardless of how the coupling was brought about. This fact is illustrated by the pilot ratings presented in table IV which are almost uniformly markedly worse for the configurations with a coupled roll-spiral mode than for the basic configuration. As for phase I, the parameters  $\omega_{RS}$ ,  $\zeta_{RS}$ , and  $\zeta_{D}$  were examined to determine whether the same trends were present for phase II as for phase I. The results showed that again, only  $\omega_{RS}$  seemed to provide even broad correlation with the degradation in the lateral-directional handling qualities.

The frequency of the coupled roll-spiral mode  $\omega_{RS}$  varied from 0.10 to 0.60 rad/sec for the various conditions covered in phase II of the study. (See table IV.) Figure 8 presents a plot of  $\omega_{RS}$  against pilot rating for the various configurations evaluated, and with the exception of five configurations, these results agree with the conclusion drawn from the results obtained during phase I; that is, no unacceptable pilot ratings were assigned to configurations having an  $\omega_{RS}$  greater than 0.35 rad/sec. The only reason that can be offered as to why these five conditions  $(\omega_{RS} > 0.35)$  were assigned unacceptable pilot ratings is that either  $\zeta_D$  or  $\zeta_{RS}$  was what might be considered to be relatively low for all five conditions. (See configurations II-11, II-15, II-18, II-19, and II-28 in table IV.)

As stated previously, for certain configurations "flown" during phase II, a landing approach was made under instrument conditions to determine whether the initial pilot assessment and rating would change for a more precise piloting task. Figure 9 shows time histories of the landing approach for three representative configurations. Figure 9(a) is an approach made with the basic configuration (configuration II-1). Pilot A assigned a rating of  $2\frac{1}{2}$  and pilot B, a rating of  $3\frac{1}{2}$  to the lateral-directional handling qualities of this configuration during the air work, and these ratings remained unchanged for the ILS approach task. Figure 9(b) presents an approach time history for configuration II-10, which represents a condition in which the roll and spiral modes have coupled, with  $\omega_{RS} = 0.10 \text{ rad/sec.}$  This configuration was assigned a pilot rating of 9 and 10 by pilots A and B, respectively, during the air work, and both pilots assigned a rating of 10 to this configuration during the ILS approach. Comparison of figures 9(a) and 9(b) shows that configuration II-10 was uncontrollable, or at least uncontrollable to the extent that it could not be landed safely. Figure 9(c) presents an approach time history for configuration II-17, which represents a condition in which the roll and spiral modes have coupled, with  $\omega_{RS} = 0.40 \text{ rad/sec}$ . This configuration was assigned a pilot rating of 4 and 6 by pilots A and B, respectively, during the air work and a pilot rating of 4 and 5, respectively, during the ILS approach. This time history (fig. 9(c)) shows that the pilot "flew" configuration II-17 on the approach more precisely than he did the configuration of figure 9(b) and slightly less precisely and with slightly more effort than he did the basic configuration of figure 9(a).

Although the fact is not necessarily reflected in the pilot ratings assigned to these three representative configurations, the difference in the pilot ratings assigned to a given configuration during the air work and the ratings assigned to the same configuration during the ILS approach task were fairly consistent; sometimes the ratings did not change and sometimes the ratings were as much as 1 pilot rating better or worse for the ILS approach. The piloting tasks used during the present study were therefore concluded to be adequate for evaluating the lateral-directional handling qualities of the various configurations investigated.

#### General Comments on the Effects of Turbulence

The scope of the present investigation did not include the effects of atmospheric turbulence, but some general comments on the possible effects of turbulence on an aircraft that possesses the unconventional dynamic stability characteristics discussed in the Introduction are reviewed. The following discussion applies only to the situation in which the roll and spiral modes are coupled.

When there is no atmospheric turbulence, as was the case in the present investigation, and a pilot elects to roll the aircraft to a predetermined bank angle, the pilot's initial lateral control input must be countered, in most cases, by an opposite control input

because of the apparent lack of a sufficient amount of roll damping. Then generally, the pilot must make a series of smaller corrections in both directions in an attempt to stabilize the aircraft at the prescribed bank angle. The pilots believe that if the aircraft is being flown in turbulence, the pilot would not be able to provide the desired roll damping by making these small corrective inputs. It is believed that in turbulence, the lateral oscillations that are triggered by the lateral control inputs would be aggravated, and as a result, the pilot would tend to overcontrol during his manual damping process; thus, pilot-induced oscillations would occur. For such a set of circumstances, however, if the pilot released the controls, the pilot inputs to the oscillation would cease and the strong apparent spiral stability, which is found in the cases in which  $\omega_{\rm RS} > 0.35~{\rm rad/sec}$ , would return the airplane to a wings-level condition with the minimum of lateral oscillations. From these considerations, it is concluded that the already marginal configurations, without turbulence, could be degraded by a pilot rating of 1 or 2 if turbulence were added to the problem.

#### Validity of Fixed-Base Simulation Results

On a fixed-base simulator most pilot cues that the pilot would have on a motion simulator or an in-flight simulator are not present. On the basis of limited results available from programs which permit direct comparison, it appears that when a pilot's rating of the flying qualities of a given airplane are good, the results will be the same whether a fixed-base simulator or an in-flight simulator is used. As the characteristics and ratings become more marginal, however, the ratings obtained from the two methods will differ, the in-flight or motion simulator results being rated better than the fixed-base simulator results.

With these points in mind, it could be said that the fixed-base simulator results presented in the present report are conservative. That is, since most of the conditions tested received marginally acceptable or marginally unacceptable pilot ratings, if these same conditions existed for an in-flight simulator program or if these conditions existed on an actual aircraft, the marginally unacceptable conditions could very well become acceptable; furthermore, the acceptable conditions could conceivably become satisfactory.

## Comments on Piloting Techniques Required When a Coupled Roll-Spiral Oscillatory Mode Is Experienced

As stated previously, when the roll and spiral modes couple and form a second oscillatory mode, in addition to the conventional Dutch roll oscillatory mode, the pilot's control of bank angle is seriously affected. (When the coupled roll-spiral mode is experienced, the pilot may see the ailerons commanding either roll acceleration or roll position, whereas he normally expects ailerons to command roll rate.)

Throughout the test program the pilots stated that in order for them to maintain control of the aircraft during roll maneuvers, for most of the configurations they were required (1) to use very small lateral control inputs when attempting to roll to a desired bank angle, and (2) to use no rudder inputs during these rolling maneuvers. In regard to the requirement of using small lateral control inputs for roll maneuvers one pilot stated: "When the roll and spiral modes have coupled, the response resulting from a lateral input appears to have low or zero roll damping causing the pilot to 'check' or reverse all lateral inputs in order to manually damp the rolling motion. The checking inputs required to stop the bank-angle change create an oscillation, or a series of oscillations, in roll. There is a definite limit to the size of these checking inputs without making the oscillations become divergent. Therefore, the only thing the pilot can do is forget a desired bank angle and simply get the oscillations stopped at any bank angle. Then — the pilot might be able to roll very slowly to the desired attitude." The same pilot also stated: "Any amount of spiral stability or instability is detrimental to precise bank-angle control since it caused inputs which increased the chances of exciting the oscillations in roll."

In an attempt to understand further why the pilots were required to use small lateral inputs during roll maneuvers, an analysis of the pilot-airplane combination was made with the root-locus technique to determine the closed-loop dynamic characteristics. For the present study, the dynamic representation of the pilot was a simplified version of the technique used in reference 4 in that the pilot was represented as being a pure gain; that is, the pilot actuates the lateral control proportionally to the error in bank angle. The method used may be of questionable validity for the wide range of lateral characteristics examined, but it does provide a reasonable approximation to the possible piloting difficulties in roll control.

Three representative configurations from phase I of this investigation are used to illustrate why the pilot is required to use small lateral control inputs during roll maneuvers. The configurations used were the basic configuration I-1 and configurations I-22 and I-17, and the results are presented in figure 10. A plot of the locus of closed-loop roots for variations in pilot gain of configuration I-1 is presented in figure 10(a) and indicates that either small or large lateral control inputs could be used for roll maneuvers since for all pilot gains, all modes remain in the stable portion of the complex plane and are well damped. The root locus for a variation in pilot gain for configuration I-22 is presented in figure 10(b). Configuration I-22 represents a condition in which the roll and spiral modes have coupled and formed a low-frequency oscillation ( $\omega_{RS} = 0.10 \text{ rad/sec}$ ). It is seen from figure 10(b) that if the pilot disturbs the aircraft in roll and uses anything other than small inputs, the coupled roll-spiral oscillatory mode will become unstable ( $\zeta_{RS}^{\prime}$  becomes negative). Configuration I-17 represents a condition in which the roll and spiral modes have coupled and formed an oscillation with a frequency  $\omega_{RS}$  of

0.40 rad/sec. Figure 10(c) presents the root locus for a variation in pilot gain for configuration I-17 and shows that although the oscillation does not become unstable as the pilot gain is increased, the higher the pilot gain the lower the damping of the oscillation  $\zeta'_{RS}$  will be.

From these results it is concluded that when the roll and spiral modes couple and form a second oscillatory mode, in addition to the conventional Dutch roll mode, the pilots must use small lateral control inputs during roll maneuvers in order for the resulting oscillation to be as well damped as possible. It is possible however that this reasoning will not be true when  $\omega_{RS}$  is greater than 1 rad/sec. As stated previously, when  $\omega_{RS}$  is very high ( $\omega_{RS} \ge 1.0$  rad/sec), the pilot may give the configuration an unacceptable rating not only because of the strong apparent spiral stability but also because the aileron control effectiveness will appear to be low for the higher  $\omega_{RS}$  values.

For most of the configurations evaluated during the present investigation, the pilots chose not to use the rudder during roll maneuvers. The pilots stated that although sideslip was generated in using ailerons alone during roll maneuvers, the control task was much easier if the rudder was not used. One pilot stated: "The rudder acts as a powerful roll control and it simply doesn't make sense to try to use two controls simultaneously for the same thing. It is very difficult to anticipate the roll resulting from an aileron input alone, and when you overlay the strong roll control afforded by the rudder, you have an impossible control situation."

#### CONCLUDING REMARKS

The results obtained during a fixed-base simulator program conducted as a preliminary determination of the effects of a coupled roll spiral mode on lateral-directional handling qualities may be summarized as follows:

When the conventional roll and spiral modes couple, the lateral-directional handling qualities are seriously degraded regardless of how the coupling was brought about, that is, regardless of which aerodynamic derivative or combination of derivatives caused the two modes to couple.

The comments made by the pilots and the pilot ratings assigned to the various configurations correlated somewhat in terms of the frequency of the roll-spiral mode in that "acceptable" pilot ratings  $\left(6\frac{1}{2} \text{ or less}\right)$  were more probable if the frequency of the coupled roll-spiral oscillatory mode was greater than 0.35 rad/sec, and indications were that this frequency should probably not be greater than approximately 1.0 rad/sec.

Generally, the higher the damping ratio of the coupled roll-spiral oscillatory mode and the damping ratio of the conventional Dutch roll mode, the better the possibility is of having acceptable handling qualities. However, there did not seem to be any definite correlation regarding the required magnitudes of the damping ratio of either mode.

When the roll and spiral modes couple and form a second oscillatory mode the pilot must use small lateral control inputs during roll maneuvers in order for the ensuing motion to be as well damped as possible.

Although sideslip was generated in using ailerons alone during roll maneuvers, the pilots found the control task to be much more difficult if the rudder was used in an attempt to achieve coordination.

$$\dot{\mathbf{u}} = -\mathbf{g} \ \sin \ \theta + \mathbf{vr} \ - \ \mathbf{wq} \ + \frac{\rho \mathbf{V^2} \mathbf{S}}{2\mathbf{m}} \left( \mathbf{C_X} + \mathbf{C_{X_{\delta_e}}} \delta_\mathbf{e} \ + \mathbf{C_{X_{\delta_s}}} \delta_\mathbf{s} \right) + \frac{\mathbf{T}}{\mathbf{m}}$$

$$\dot{\mathbf{w}} = \mathbf{g} \cos \theta \cos \phi + \mathbf{u}\mathbf{q} - \mathbf{v}\mathbf{p} + \frac{\rho \mathbf{V^2} \mathbf{S}}{2\mathbf{m}} \left( \mathbf{C}_{\mathbf{Z}} + \mathbf{C}_{\mathbf{Z}_{\delta_{\mathbf{e}}}} \delta_{\mathbf{e}} + \mathbf{C}_{\mathbf{Z}_{\delta_{\mathbf{S}}}} \delta_{\mathbf{s}} \right)$$

The following formulas were also used:

$$V = (u^2 + v^2 + w^2)^{1/2}$$

$$\alpha = \tan^{-1} \frac{\mathbf{w}}{\mathbf{u}}$$

$$\beta = \sin^{-1} \frac{\mathbf{v}}{\mathbf{V}}$$

#### **APPENDIX**

$$\dot{\theta} = q \cos \phi - r \sin \phi$$

$$\dot{\phi} = p + q \tan \theta \sin \phi + r \tan \theta \cos \phi$$

$$\dot{\psi} = \frac{\mathbf{r} \cos \phi + \mathbf{q} \sin \phi}{\cos \theta}$$

$$\dot{\mathbf{h}} = \mathbf{u} \sin \theta - \mathbf{v} \cos \theta \sin \phi - \mathbf{w} \cos \theta \cos \phi$$

$$a_n = -\frac{\dot{w} - uq + vp - g \cos \theta \cos \phi}{g}$$

$$\mathbf{a}_{\mathbf{y}} = \frac{\dot{\mathbf{v}} - \mathbf{w}\mathbf{p} + \mathbf{u}\mathbf{r} - \mathbf{g} \cos \theta \sin \phi}{\mathbf{g}}$$

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

- NATIONAL AERONAUTICS AND SPACE ACT OF 1958

# NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

#### TECHNICAL MEMORANDUMS:

Information receiving limited distribution because of preliminary data, security classification, or other reasons.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

### TECHNOLOGY UTILIZATION

PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Notes, and Technology Surveys.

Details on the availability of these publications may be obtained from:
